Chlorophylls and Carotenoids: Measurement and Characterization by UV-VIS Spectroscopy

The quantitative determination of chlorophyll (Chl) \(a\), Chl \(b\), and carotenoids in a whole-pigment extract of green plant tissue by UV-VIS spectroscopy is complicated by the choice of sample, solvent system, and spectrophotometer used. The various plant pigments absorb light in overlapping spectral regions, depending on the system selected. This unit discusses methods used to account for such overlap by applying equations for accurate quantitative determination of Chl \(a\), Chl \(b\), and total carotenoids in the same pigment extract of leaves or fruits. General information on the spectroscopic characteristics of Chl \(a\) and Chl \(b\), their specific absorption coefficients, and their quantitative determination in a whole-pigment extract of green plant tissues can be found in Šesták (1971) and Lichtenhaler (1987). For Chl structures, see UNIT F4.1.

**ABSORPTION MAXIMA**

Figure F4.3.1 shows the absorption spectrum of isolated Chl \(a\) and Chl \(b\) in diethyl ether. Chl \(a\) and \(b\) absorb with narrow bands (maxima) in the blue (near 428 and 435 nm) and red (near 661 and 642 nm) spectral ranges. The isolated yellow carotenoids have a broad absorption with three maxima or shoulders in the blue spectral range between 400 and 500 nm (Fig. F4.3.2).

The absorption maxima of extracted pigments strongly depend on the type of solvent and, to some degree, on the type of spectrophotometer used. For example, with increasing polarity of the solvent, the red absorption maximum of Chl \(a\) shifts from 660 to 665 nm, and the blue absorption maximum from 428 to 432 nm. The same also applies to Chl \(b\), which shifts from 642 to 652 nm and 452 to 469 nm (see, e.g., Fig. F4.3.3 and Table F4.3.1, and Lichtenhaler, 1987). These wavelength shifts of the absorption maxima are correlated with changes in the absorption coefficients used for the quantitative determination of Chls \(a\) and \(b\) and carotenoids. For these reasons, the absorbance readings of a pigment extract must be performed at the correct wavelength position, i.e., the maxima of pure Chl \(a\) and pure Chl \(b\) in a particular solvent. Moreover, the solvent-specific extinction coefficients have to be considered by applying the corresponding equations for calculation of the pigment content. Minor differences in the positions of the wavelength maxima also exist, depending on the spectrophotometer type used. Thus, the wavelength position can differ by 1.0 or 1.5 nm.

![Figure F4.3.1](image)

**Figure F4.3.1** Absorption spectra of freshly isolated Chl \(a\) and Chl \(b\) in diethyl ether (pure solvent). The spectra were measured 40 min after extraction of pigments from leaves and 3 min after eluting the two Chls with diethyl ether from a TLC plate.

In order to perform spectroscopic measurements of green plant tissue extracts in the right maximum regions, one should determine the maximum red spectral position of pure Chl $a$ and pure Chl $b$ solutions with one's own spectrophotometer and compare them with those from the literature, given in Table F4.3.1. For a wavelength deviation of more than 1 nm, one should measure the absorbance of the pigment extract using these self-detected maxima rather than the literature values. The same equations for the particular solvent can be applied as long as wavelength positions differ by no more than 2 nm. At a deviation of $>2$ nm, either the spectrophotometer needs wavelength adjustment or a wrong, impure solvent has been applied. For the determination of carotenoids in the same extract solution, the wavelength position of 470 nm may be maintained, since a 1-nm shift has much less influence on the total carotenoid level than on the individual levels of Chls $a$ and $b$.

**ABSORPTION SPECTRA**

The absorption spectrum of an extract of a green leaf containing a mixture of Chls $a$ and $b$ and total carotenoids (Fig. F4.3.4) is dominated by the absorption of Chl $a$ at $A_{425}$ (blue).

*Units of absorbance coefficients are given in liter g$^{-1}$ cm$^{-1}$. $\alpha_{a,\text{max}}$ is the specific absorbance coefficient of Chl $a$ at its red maximum; $\alpha_{a,\text{max}}$ is the specific absorbance coefficient of Chl $a$ at the red maximum of Chl $b$; $\alpha_{a,470}$ is the specific absorbance coefficient of Chl $a$ at 470 nm; $\alpha_{b,+C470}$ is the specific absorbance coefficient of the sum of xanthophylls and carotenoids at 470 nm.
and $A_{661}$ (red). Chl b and the carotenoids absorb broadly in the blue region (400 to 500 nm).

A plant sample homogenized with an organic solvent is usually turbid and must be filtered or centrifuged to become fully transparent (see UNIT F4.2). Turbidity and light scattering lead to a higher absorption between 400 and 800 nm, with a slight but continuous increase towards shorter wavelengths (Fig. F4.3.5). Thus, measuring a turbid extract leads to an overestimation of the pigment levels, especially for Chl b and total carotenoids. Turbidity can be checked by measuring $A_{350}$ and $A_{530}$. For a fully transparent leaf pigment extract, $A_{350}$ should equal zero, since Chls a and b and carotenoids do not absorb in this region. $A_{530}$ readings for extracts of green plant tissue should be $<$10% of the main Chl absorbance in the red maximum near 661 nm (diethyl ether) or 650 nm (ethanol), as shown in Figures F4.3.4 and F4.3.5.

**ACCURACY OF SPECTROSCOPIC MEASUREMENTS**

In order to have an exact spectroscopic measurement of absorbances, one must consider the absorbance range in which readings are made. Absorbance should be measured between 0.3 and 0.85. Leaf extracts with an absorbance $<$0.3 in the red region do not yield correct pigment values. There are several interfering factors, such as a baseline that is not fully zeroed. Thus, values $<$0.3, whether read by the experimenter or given as digital values by the instrument, are not acceptable. Absorbance values $>$0.9 may indicate problems with the accuracy of the detector (e.g., a photomultiplier). Since the detector system examines the transmitted light of the cuvette, the absorbance is calculated from this value. When transferring the linear transmission unit to the logarithmic absorbance unit, the accuracy is exponentially reduced with rising values.

![Figure F4.3.3](image)

**Figure F4.3.3** Differences in the absorption spectra of Chl a and Chl b in diethyl ether and 95% aqueous ethanol. For the more polar solvent (95% ethanol; broken line), the absorbance (extinction) in the blue and red absorption maxima of both Chls are decreased compared to values obtained using the less polar solvent diethyl ether (black), and the wavelength positions of the maxima are shifted to the right. For a better comparison, the absorbances in the red maxima were set at the same values.

**Chlorophylls**

F4.3.3

Current Protocols in Food Analytical Chemistry

Supplement 1
Figure F4.3.4 Absorption spectra of pigments from a green tobacco leaf extracted with 100% acetone. The leaf extract was measured directly after extracting the leaf. Chl \( a \), Chl \( b \), and the carotenoids \( \beta \)-carotene (\( \beta \)-C) and lutein (Lut) were measured after separation by TLC.

Figure F4.3.5 Absorption spectra of a leaf extract before (turbid) and after (transparent) centrifugation in 100% acetone. The difference spectrum between the two extracts represents the spectrum of turbidity.
For absorbance values <0.3, one should try
to concentrate the extract (e.g., by evaporation),
make a new extract using more plant material
and less solvent, or extract the pigments in a
separatory funnel into a small volume of a
hydrophobic solvent in the epiphase. Various
spectrophotometers are constructed to measure
absorbance (extinction) values only up to 1.0
(i.e., a transmittance of 10%). In such cases, an
absorbance >0.85 is not suitable, and the extract
solution should be diluted to obtain valid Chl
b and carotenoid values. In both cases, care
must be taken to ensure that the final volume
of the extract solution is carefully recorded and
considered in the calculation of total Chls and
carotenoids.

The extinction coefficients and the equa-
tions used and established by Arnon (1949) are
not correct. They provide only a rough estimate
of Chl a and b levels and yield inaccurate Chl
b values, and consequently, incorrect values
for the Chl alb ratio. They have been redeter-
mined by Lichtenhaler (1987) using the extinc-
tion coefficients of Smith and Benitez (1955)
for pure Chl a and Chl b in diethyl ether, which
were found to be correct in the red absorption
maxima at 661 and 642 nm, respectively, for
purified Chls. The relative absorptions of Chl
a and Chl b at other wavelengths in other
organic solvents have been redetermined using
modern high-resolution spectrophotometers.

To exactly determine carotenoids by meas-
uring \( A_{x} \), one needs to know the exact level
of Chl b, which (in contrast to Chl a) also
absorbs considerably at this wavelength (Fig.
F.4.3.1). If Chl b is overestimated, the level of
total carotenoids becomes too low, and vice
versa. With the redetermined extinction coeffi-
cients, the new equations permit the determina-
tion of total carotenoids in addition to Chl a
and Chl b in the same green tissue extract solutions.

QUANTIFICATION OF PIGMENTS

The basis for spectroscopic quantification of pigments is the Lambert-Beer law, which
defines the absorbance of a solution with re-
spect to the specific light absorption character-
istic of an individual dissolved compound:

\[
A = \alpha c_x d \text{ or } A = \varepsilon c_m d
\]

where \( A \) is absorbance (dimensionless), \( \alpha \) is the
specific absorbance coefficient in liter g\(^{-1}\) cm\(^{-1}\),
\( \varepsilon \) is the molar absorbance coefficient in liter
mol\(^{-1}\) cm\(^{-1}\), \( c_x \) is the weight concentration in g
liter\(^{-1}\), and \( c_m \) is the molar concentration in mol
liter\(^{-1}\), and \( d \) is the path length of the cuvette in
cm, usually 1 cm.

This original Lambert-Beer law can only be
applied for one isolated pigment. Absorbance
coefficients taken from the literature (Table
F.4.3.1) are valid only for one substance (e.g.,
Chl a) using one solvent (e.g., 100% acetone)
and one wavelength (e.g., 661.6 nm). Changes
in substance, solvent, or wavelength lead to
changes in the absorbance coefficient.

When the concentration of Chl a and Chl b
is determined from a pigment extract containing
both Chls, the equation derived from the Lam-
bert-Beer law becomes more complex. The ab-
sorbance is then expressed as the sum of the
absorptions of Chl a and Chl b. Thus, the
absorbance of Chl b contributes to the absorb-
ance of Chl a at the Chl a maximum, and vice
versa:

\[
A_{\text{max}, a} = A_{(a)\text{max}, a} + A_{(b)\text{max}, a} =
\left( \alpha_{(a)\text{max}, a} \times c_{a, a} \times d \right) + \left( \alpha_{(b)\text{max}, a} \times c_{a, b} \times d \right)
\]

\[
A_{\text{max}, b} = A_{(a)\text{max}, b} + A_{(b)\text{max}, b} =
\left( \alpha_{(a)\text{max}, b} \times c_{a, a} \times d \right) + \left( \alpha_{(b)\text{max}, b} \times c_{a, b} \times d \right)
\]

The concentrations for Chl a (\( c_a \)) and Chl b
(\( c_b \)) are then given by a different equation,
where the specific contribution of Chl b to the
Chl a maximum and of Chl a to the Chl b
maximum are subtracted. The following equa-
tions contain the denominator \( z \), a term formed
from the four extinction coefficients of Chl a
and Chl b. The light path length (usually 1 cm)
is omitted here:

\[
c_a = \left[ \frac{\alpha_{(a)\text{max}, a} \times A_{\text{max}, a}}{z} \right] - \left[ \frac{\alpha_{(b)\text{max}, a} \times A_{\text{max}, b}}{z} \right]
\]

\[
c_b = \left[ \frac{\alpha_{(a)\text{max}, b} \times A_{\text{max}, a}}{z} \right] - \left[ \frac{\alpha_{(b)\text{max}, b} \times A_{\text{max}, a}}{z} \right]
\]

\[
z = \left( \alpha_{(a)\text{max}, a} \times \alpha_{(b)\text{max}, a} \right) - \left( \alpha_{(a)\text{max}, b} \times \alpha_{(b)\text{max}, b} \right)
\]

DETERMINATION OF TOTAL
CAROTENOIDs

In an extract of plant material containing
carotenoids (x + c = xanthophylls and caro-
tenes) in addition to Chls, \( A_{x,70} \) (the carotenoid
region) is determined as the sum of specific
absorbances for Chl a, Chl b, and total carotenoids:

\[ A_{470} = A_{\text{a+c}} + A_{\text{a}} + A_{\text{b}} + A_{\text{c}} \]

From this follows, according to the Lambert-Beer law:

\[ A_{\text{a+c}} = \alpha \cdot (a+c) \cdot c_a \times d \]
\[ A_{\text{a}} = \alpha \cdot a \cdot c_a \times d \]
\[ A_{\text{b}} = \alpha \cdot b \cdot c_b \times d \]
\[ A_{\text{c}} = \alpha \cdot c \times c_a \times d \]

The concentration of carotenoids \( c_{\text{a+c}} \) is then given by the following equation, which has been reduced using \( d = 1 \) cm:

\[ c_{\text{a+c}} = \frac{A_{\text{a+c}} - (\alpha \cdot (a+c) \cdot c_a) - (\alpha \cdot a \cdot c_a)}{\alpha \cdot c} \]

The concentrations for Chl a (\( c_a \)), Chl b (\( c_b \)), and the sum of leaf carotenoids (\( c_{\text{a+c}} \)) can be calculated with the following equations given for different solvents, where the pigment concentrations are given in \( \mu g/ml \) extract solution.

**Diethyl ether (pure solvent):**

\[ c_a (\mu g/ml) = 10.05 \cdot A_{\text{a+c}} - 0.97 \cdot A_{\text{a+b}} \]
\[ c_b (\mu g/ml) = 16.36 \cdot A_{\text{a+b2}} - 2.43 \cdot A_{\text{a+c}} \]
\[ c_{\text{a+c}} (\mu g/ml) = (1000 \cdot A_{\text{a+c}} - 1.43 \cdot c_a - 35.87 \cdot c_b) / 205 \]

**Diethyl ether (water free):**

\[ c_a (\mu g/ml) = 9.93 \cdot A_{\text{a+c}} - 0.75 \cdot A_{\text{a+b}} \]
\[ c_b (\mu g/ml) = 16.23 \cdot A_{\text{a+b2}} - 2.42 \cdot A_{\text{a+c}} \]
\[ c_{\text{a+c}} (\mu g/ml) = (1000 \cdot A_{\text{a+c}} - 1.30 \cdot c_a - 33.12 \cdot c_b) / 213 \]

**Diethyl ether (water saturated):**

\[ c_a (\mu g/ml) = 10.36 \cdot A_{\text{a+b2}} - 1.28 \cdot A_{\text{a+b}} \]
\[ c_b (\mu g/ml) = 17.149 \cdot A_{\text{a+b2}} - 2.72 \cdot A_{\text{a+c}} \]
\[ c_{\text{a+c}} (\mu g/ml) = (1000 \cdot A_{\text{a+c}} - 1.38 \cdot c_a - 48.05 \cdot c_b) / 211 \]

**Ethanol with 5% (v/v) water:**

\[ c_a (\mu g/ml) = 13.36 \cdot A_{\text{a+b}} - 5.19 \cdot A_{\text{a+c}} \]
\[ c_b (\mu g/ml) = 27.43 \cdot A_{\text{a+b}} - 8.12 \cdot A_{\text{a+c}} \]
\[ c_{\text{a+c}} (\mu g/ml) = (1000 \cdot A_{\text{a+c}} - 2.13 \cdot c_a - 97.64 \cdot c_b) / 209 \]

**Acetone (pure solvent):**

\[ c_a (\mu g/ml) = 11.24 \cdot A_{\text{a+b2}} - 2.04 \cdot A_{\text{a+b}} \]
\[ c_b (\mu g/ml) = 20.13 \cdot A_{\text{a+c}} - 4.19 \cdot A_{\text{a+b}} \]
\[ c_{\text{a+c}} (\mu g/ml) = (1000 \cdot A_{\text{a+c}} - 1.90 \cdot c_a - 63.14 \cdot c_b) / 214 \]

**Acetone with 20% (v/v) water:**

\[ c_a (\mu g/ml) = 12.25 \cdot A_{\text{a+b2}} - 2.79 \cdot A_{\text{a+b}} \]
\[ c_b (\mu g/ml) = 21.50 \cdot A_{\text{a+c}} - 5.10 \cdot A_{\text{a+b}} \]
\[ c_{\text{a+c}} (\mu g/ml) = (1000 \cdot A_{\text{a+c}} - 1.82 \cdot c_a - 85.02 \cdot c_b) / 198 \]

**Methanol (pure solvent):**

\[ c_a (\mu g/ml) = 16.72 \cdot A_{\text{a+b2}} - 9.16 \cdot A_{\text{a+b}} \]
\[ c_b (\mu g/ml) = 34.09 \cdot A_{\text{a+b2}} - 15.28 \cdot A_{\text{a+c}} \]
\[ c_{\text{a+c}} (\mu g/ml) = (1000 \cdot A_{\text{a+c}} - 1.63 \cdot c_a - 104.96 \cdot c_b) / 221 \]

**Methanol with 10% (v/v) water:**

\[ c_a (\mu g/ml) = 16.82 \cdot A_{\text{a+b2}} - 9.28 \cdot A_{\text{a+b}} \]
\[ c_b (\mu g/ml) = 36.92 \cdot A_{\text{a+b2}} - 16.54 \cdot A_{\text{a+c}} \]
\[ c_{\text{a+c}} (\mu g/ml) = (1000 \cdot A_{\text{a+c}} - 1.91 \cdot c_a - 95.15 \cdot c_b) / 225 \]

**INTERPRETATION OF CHLOROPHYLL AND CAROTENOID CONTENT**

The concentration of Chl a and b in plant material can be quantified with different reference systems. Reference systems currently in use include mg Chl a+b/m² leaf area (or µg/cm² leaf area), µg Chl a+b/g dry weight, and mg Chl a+b/g fresh weight (less suitable than dry weight).

When comparing results with those of other groups or with values obtained previously, the same reference system must be applied. Changes in Chl content should be demonstrated by means of a reference that does not change, otherwise an observed variation of data may not be due to changes in Chl concentration, but instead to changes in the reference system. For instance, an increase in Chl per fresh weight (in leaves or fruits) could be solely due to a decrease in fresh weight caused by water loss. In various cases, the number of leaves, cotyledon pairs, seedlings (shoots), or fruits may be the best reference system to follow changes in pigment levels, as these numbers do not change when dry weight or leaf area vary.

The weight ratio of Chl a and Chl b (Chl a/b ratio) is an indicator of the functional pigment...

The weight ratio of Chls a and b to total carotenoids \((a+b)/(x+c)\) is an indicator of the greenness of plants. The ratio \((a+b)/(x+c)\) normally lies between 4.2 and 5 in sun leaves and sun-exposed plants, and between 5.5 and 7.0 in shade leaves and shade-exposed plants. Lower values for the ratio \((a+b)/(x+c)\) are an indicator of senescence, stress, and damage to the plant and the photosynthetic apparatus, which is expressed by a faster breakdown of Chls than carotenoids. Leaves become more yellowish-green and exhibit values for \((a+b)/(x+c)\) of 3.5, or even as low as 2.5 to 3.0 as senescence progresses. Also, during chromoplast development in ripening fruits or fruit scales, which turn from green to yellow or orange or red, the ratio \((a+b)/(x+c)\) decreases continuously and reaches values below 1.0.

Sun leaves of different trees exhibit average Chl a+b levels of 400 to 700 mg/m² leaf area (40 to 70 μg/cm²) and shade leaves have 380 to 570 mg/m² leaf area (38 to 57 μg/cm²). As sun leaves possess thicker cell walls, a lower leaf
